Abstract

Functional neuroimaging first allowed researchers to describe the functional segregation of regionally activated areas during a variety of experimental tasks. More recently, functional integration studies have described how these functionally specialized areas, interact within a highly distributed neural network. When applied to the field of neurosciences, structural equation modeling (SEM) uses theoretical and/or empirical hypotheses to estimate the effects of an experimental task within a putative network. SEM represents a linear technique for multivariate analysis of neuroimaging data and has been developed to simultaneously examine ratios of multiple causality in an experimental design; the method attempts to explain a covariance structure within an anatomical constrained model. This method, when combined with the concept of effective connectivity, can provide information on the strength and direction of the functional interactions that take place between identified brain regions of a putative network.

Keywords: Model; Network; Integration; Effective connectivity; SEM

1. Introduction

Neuroimaging has enabled great progress in the field of cognitive science. Indeed, over the last two decades, fascinating discoveries have been made in terms of the brain's structure, organization and function. Thanks to neuroscience, we can now better understand the way the brain operates when it recognizes a face [1–4], admires a work of art or learns a language [5]. Today, functional magnetic resonance imaging (fMRI) helps us locate the brain areas involved in the various forms of vision or emotion, in self-awareness and in awareness of others. On the basis of assumptions and theoretical and/or empirical models, we are now able to show how brain areas interact

with each other and how external stimuli may modulate the latter's activity [6–11]. In order to understand the various stages that lead from fMRI-measured dynamic brain activity to interpretation of a large-scale network of brain functions, we first need to examine briefly the physiological bases of the neural and hemodynamic blood-oxygen-level-dependent (BOLD) activity. Secondly, we will describe the classic statistical approach that enables measurement of brain activity in an exploratory way and the concepts of functional and effective connectivity that enable examination of the interactions between various brain areas. Thirdly, we will describe the principles behind the structural equation modeling (SEM) method that enables the analysis of interdependency relationships within a putative network of functional areas. Finally, we will emphasize the stages in SEM that must be thoroughly mastered in order to use this type of analysis correctly.

Cortical activity measured by fMRI may correspond to a cascade of neurochemical events that occur within neurons

and the glial cells (astrocytes, in particular) located near the synapses [12]. These cells play an essential role in reuptake of glutamate (the neurotransmitter) released at the synapse following a change in membrane voltage. Glutamate is quickly transported within adjacent astrocytes where it is converted into glutamine for transfer back to the neuron. This synaptic and dendritic activity, when integrated over a few millimeters of neural tissue, would display relatively weak energy efficiency (production of ATP) but would roughly reflect the slow fluctuations in local field potentials, corresponding to electric entries and their intracortical treatment [13]. Unit recordings have been used to show that the frequency of neuronal discharge is related to the fMRI signal [12]. Thus, the BOLD contrast obtained in fMRI may represent the signature of the electrical, energetic and hemodynamic consequences of brain activity. By comparison, the signals measured in electroencephalography and magnetoencephalography are closely related to neuronal currents [14] and, thus, may be more sensitive to postsynaptic activity [15]. Nevertheless, the exact physiological process leading from neuronal activity to the BOLD signal is still under investigation [16–20]. Despite a certain level of uncertainty concerning the exact nature of the microscopic mechanisms at the origin of neurovascular coupling, a perceptive or cognitive stimulation carried out in the scanner gives rise to a cascade of metabolic processes associated with neuronal activity in various areas of the brain. A hemodynamic response to this metabolic demand involves an increase in cerebral blood flow and volume, which will vary in terms of its intensity in each activated voxel. The BOLD signal will change over time according to the metabolic demand and location of the involved cerebral areas and with respect to the oxygenation conditions, cerebral blood flow and volume.

Neural assemblies, which provide a conceptual framework for the integration of distributed neural activity, are defined as distributed local networks of neurons transiently linked by reciprocal dynamic connections [7,21,22]. The emergence of a specific neuronal assembly is thought to underlie the operation of every cognitive act. Neurons that belong to a given assembly are linked by selective interactions; that is, they interact preferentially with a sub-ensemble of other neurons that are interconnected. These interactions are mediated through direct (monosynaptic) or indirect (polysynaptic) connections that are typically reciprocal [23]. On the one hand, there are reciprocal connections within the same cortical area or between areas situated at the same level of the network. On the other, there exist connections that link different levels of the network in different brain regions to the same assembly [24]. Connections of this type have been traditionally described as feedforward and feedback (or as bottom–up and top–down). These neural assemblies have a transient, dynamic existence that spans the time required to accomplish an elementary cognitive act (a fraction of a second). However, at the same time, their existence is long

enough for neural activity to propagate through the assembly, a propagation that necessarily involves cycles of reciprocal spike exchanges with transmission delays that last tens of milliseconds. Hence, the relevant variable required to describe these assemblies is not so much the individual activity of the components of the system but the dynamic nature of the links between them [25].

Emerging hypotheses in neuroscience can use fMRI to study functional interactivity. By defining neural assemblies as distributed local networks that are transiently linked by large-scale reciprocal dynamic connections, Varela et al. [25] made a clear distinction between local and large-scale networks. On one hand, a local network is defined as a patch of neural tissue that synchronizes its activity through the local cytoarchitecture, that is, groups of entities (neurons) acting together in a coherent fashion [26]. Local integration occurs over a local network distributed over an area of ~ 1 cm through monosynaptic connections with conduction delays of typically 4–6 ms [27]. For example, in columns of the primary visual cortex separated by 2–7 mm, which have nonoverlapping receptive fields, neurons that share similar feature properties tend to synchronize [28]. On the other hand, large-scale dynamic connections are defined as interactions based on large fiber pathways between regions that are located far apart from one another. Large-scale synchronization concerns neural assemblies that are further apart in the brain (>1 cm; transmission delays >8 –10 ms over polysynaptic pathways) such as, for example, assemblies between occipital and frontal lobes or across hemispheres, which are separated by dozens of milliseconds in transmission time [27].

While the segregation principle states that some functional processes specifically engage well-localized and specialized brain regions, it is now thought that brain functions are most likely to emerge through integration of information flows across distributed regions [25,29,30]. In this approach, it is not only isolated brain areas that are presumed to process information, a large-scale network (i.e., a set of brain regions interacting in a coherent and dynamic way) is too. Hence, according to the functional integration concept, cortical areas and, thus, functions are integrated within specific dynamic networks. This concept supposes that there is dynamic interaction between interconnected, active areas and, thus, that the brain areas are expressed as networks within integrated systems. In such a system, localized areas are included in networks, which become dynamic according to the cognitive task. Brain areas underlie several functions and can belong successively to several different functional networks. In other words, a given brain area does not have a single function; its resources can be exploited in several different cognitive strategies. The principle of functional integration (which is also known in the field of electrophysiology) was used to analyze the event potentials obtained from multipolar recordings [31]. Thus, based on the functional integration principle, the relationships between several brain areas may be examined.

2. Exploration of the effective connectivity

Effective connectivity is closer to the intuitive notion of a connection and can be defined as the influence that one neural system exerts over another, either at a synaptic level (synaptic efficacy) or at a cortical level [11,32]. In electrophysiology, there is a close relationship between effective connectivity and synaptic efficacy [33]. Effective connectivity can be estimated from SEM, a linear technique that can be used to test whether a theoretical model seeking to explain a network of relationships can actually fit the relationships estimated from the observed data. In the case of fMRI, the theoretical model is an anatomical constrained model and the data are interregional covariances of activity [34]. To describe a functional network, network nodes (active areas) and anatomical connections (fibers) must be proposed in conjunction with SEM in order to model interregional covariances and determine the intensity of the connections. Effective connectivity will represent the dynamic influence that cortical and subcortical regions exert on each other via a putative network of interdependent areas. An increasing number of PET, fMRI and transcranial magnetic stimulation studies have used the SEM method to investigate large-scale functional brain networks [35–38] and show specific networks involved in working memory [39–45], within attentional processes [46–49], face perception [4,50,51], motor movement processing [52–58], language [8,59] or with the processing of painful stimuli [60].

3. Path model construction and SEM

SEM can be performed with a number of different software programs. The most popular are LISREL (<http://www.ssicentral.com/lisrel>), EQS (<http://www.mvsoft.com/products.htm>) and AMOS (<http://www.spss.com/amos/>). The path model is based on a hypothesized network restricted to different topologically distinct brain regions. We used SEM to construct a pathway model that could account for fMRI data in all regions of interest.

3.1. Basic concepts

SEM is a technique of multivariate statistical analysis that can be used on fMRI data. Originally, SEM was developed to analyze psychometric and economic data. Structural models make it possible to analyze linear relationships between variables from the analysis of the covariance among the variables. Structural models evolved from two principal methods of analyses: (a) factorial analysis (for a review, see Ref. [61]) and (b) multiple regression or causal path analysis, a method developed in the 1930s by Wright (for a review, see Ref. [62]). Structural models examine, simultaneously, multiple sources of influence on the dependent variable in an experiment [63,64]. When applied to fMRI data, SEM allows modeling of paths of connection between cortical areas and reveals relations, interdependencies and covariance among the various cortical areas. Given an anatomical model, SEM shows the effects of an

experimental task on a specific network of connections [32,65–67]. In this type of statistical analysis, variables are considered in terms of the structure of their covariances. Thus, SEM allows one to infer interregional dependencies (inter-activities) between various cerebral cortical areas.

SEM methods, in comparison with classical approaches such as linear regression, allow one to simultaneously analyze several types of interrelationships between variables in an experiment [6,11,20,68]. Variables can be directly observable or indirectly observable (latent), that is, variables that are inferred from multiple indicators. This article discusses only directly observable variables.

- Variables may be directly related or indirectly related. For example, the effect of A on C may be direct, ($A \rightarrow C$), or it may be indirect or mediated by B, ($A \rightarrow B \rightarrow C$). SEM can distinguish direct from indirect relations.
- A relation between variables may be recursive. That is, the effect of A on B, ($A \rightarrow B$), may be different from the effect of B on A, ($B \rightarrow A$).
- Relations between variables may be reciprocal. For example, an important question often asked is “Which of two variables acts more on a third one?” SEM answers the question by analyzing the relations on a hierarchical basis.
- The nature of the relation between variables is given by the regression coefficient; it describes how much the dependent variable changes when an independent variable changes by one unit. SEM directly integrates the errors of measurement into a statistical model; by doing so, the estimates of regression coefficients are more precise than they are with classical methods such as multiple regression, factorial analysis, analysis of variance or discriminant analysis. The older methods examine only one linear relation at the same time between independent and dependent variables and do so only within a range of values set by the researcher [32].

Contrary to classical methods, SEM is interested in a structure of variances/covariances in a dataset of observed variables and it will try to predict dependences among the variables (see Fig. 1). In other words, SEM seeks to explain as much of the variance in dependent variables as it can from the simultaneous measurement of the variances of independent variables that are included in the model. Similarly, SEM incorporates errors of measurement (residual variances) of the independent variables into the calculation of estimate, which reinforces the statistical power of the method and provides more precise estimates of b coefficients (coefficients of regression). Thus, one can validate a model of measurement from a theoretical model or empirical data [44].

3.2. Constructing and specifying the theoretical model

Relationships between each variable should be supported by the hypotheses of a theoretical framework and/or

empirical observations. It is important not to voluntarily omit significant explanatory variables in the model of analysis (error of the model specification) at the risk of under- or overestimating (biasing) the effects of the other variables that are retained in the model. The stronger the correlation between these variables, the more the coefficients of regression will be biased. The principle of parsimony requires that we identify and retain explanatory variables and the most relevant relations or paths among them to explain a phenomenon. We can do so by first testing an initial, economical model and then making it more complex, if necessary. The objective is to retain the fewest number of variables and interrelationships (paths) that explain as much as the variance in the phenomenon as possible.

The specification step consists of constructing a diagram of relations (e.g., Fig. 1) and then determining the structural model by answering various questions: Which linear relations between variables must be tested? What is the nature of their relationship (one-way, reciprocal/recursive)? What are the different parameters to be estimated (coefficients of regression, covariances)? Which parameters are fixed, free or constrained?

Fig. 1, adapted from Ref. [4], illustrates an example of SEM. We examined effective connectivity within an emotional network composed of three brain areas involved in processing fearful faces: orbitofrontal (OFC or VAR1), anterior cingulate cortex (ACC or VAR2) and amygdala (AMY or VAR3). Their experimental manipulation consisted of two tasks, an incidental perception task (gender identification) and an intentional detection task (effortful discrimination), each task performed with three facial expressions: fearful, neutral and ambiguous. Subjects were scanned while performing the tasks. Effective connectivity between the three brain areas was assessed using SEM. The reader can be just referred to the original paper [4].

Results show that the hypothetical network fits the experimental data for both tasks, in both hemispheres. The comparison between Task 1 and Task 2 reveals significant differences in strength and direction of the connectivity patterns for the left hemisphere and, to a lesser extent, for the right hemisphere. The path coefficient analysis suggests that during incidental perception, the fearful information generated in AMY reaches the OFC through the ACC, while in the intentional perception task, fearful information generated in

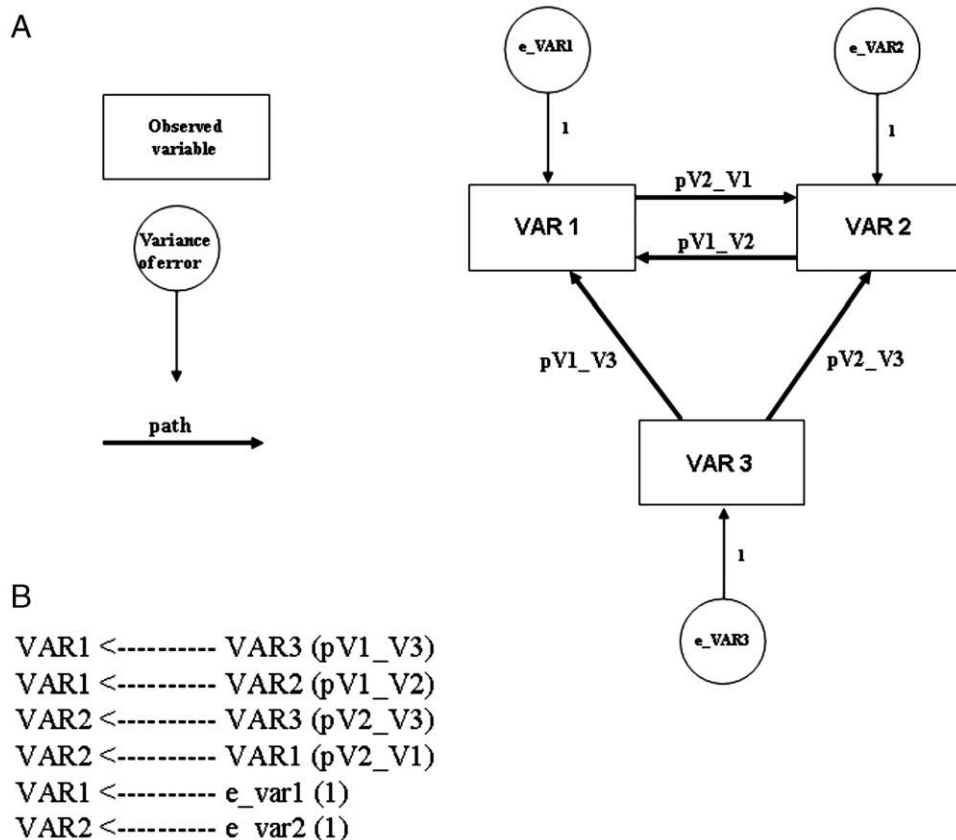

Fig. 1. (A) Structural model with three regions. The three observed variables VAR1 (OFC), VAR2 (ACC) and VAR3 (AMY) are represented by rectangles; each of them is connected with an error term (variance not explained by the model). The same model is used for both tasks; only the path coefficients and the variances of error change between the two tasks. (B) The relationships between the observed variables are described by an arrow pointing towards the dependent variable. Brackets after the relation represent the constraint on the parameter; for example, (pV1_V3) indicates a free parameter to estimate and (1) indicates a fixed parameter. Some parameters are constrained or fixed to equal 1.0 (in this example, the parameter relating the error variance to its variable) so that the system of equations can be identified (adapted from Ref. [4]).

AMY follows a reverse route, from the OFC to the ACC. The findings confirm differential brain connectivity during incidental and intentional processing of fearful faces.

Free parameters are those whose value is unknown and which the algorithm has to estimate. Constrained parameters are free parameters on which the model imposes a constraint, often a constraint of equality between their values. Fixed parameters indicate potential paths that will not be estimated; they are fixed at zero and, thus, do not enter in the procedure of calculation. This diagram of relations (Fig. 1) is then transposed into linear equations as:

$$\begin{aligned} \text{VAR1} &= \mathbf{pV1_V3} * \text{VAR3} + \mathbf{pV1_V2} * \text{VAR2} + 1 * e_{\text{var1}} \\ \text{VAR2} &= \mathbf{pV2_V3} * \text{VAR3} + \mathbf{pV2_V1} * \text{VAR1} + 1 * e_{\text{var2}} \end{aligned}$$

The parameters are named, in boldface, by the variables that are related: It is convenient to put the influenced variable (effect) first and the influencing variable (cause) second.

From the linear equations, we can calculate the proportion of variance in the observed variables (e.g., VAR1) that is explained by the variables on the right side of the equation. The more closely the proportion of the explained variance approaches 1.0, the greater our confidence that we have identified the variables that are associated with the observed variable. Conversely, when the proportion of explained variance approaches zero, we have little confidence that the variables are linearly related.

3.3. Estimates of the theoretical model

SEM works with a matrix of covariances rather than with a matrix of correlations. This choice implies that the value of estimated coefficients will depend on the unit of measure of the variables (like the b coefficients in the multiple regression analysis). Standardizing the values of the coefficients gives them all the same metric, 1.0, which makes them easier to interpret. The standardized values are equivalent to β coefficients of simple or multiple regressions.

3.3.1. Calculating the model parameters

Only relationships proposed by the theoretical model are examined. The estimate of the model parameters (covariances, correlations, coefficients of regression) by maximum likelihood (robust estimator) is achieved with an iterative process guided by the decrease in the value of the difference between the observed covariance matrix and the theoretical covariance matrix calculated from the parameters included in the model. An iterative procedure adjusts the predictive values with the observed values. The estimator is consistent when the predictive values converge towards the observed true values of parameters.

3.3.2. Testing hypothesis

At the end of the estimation process, a test of fit is applied: In this test, the value of the function representing the difference between the observed and predicted matrix is used to compute an indicator called χ^2 , which follows a chi-square distribution. The null hypothesis is that there is no

difference (a gap of zero) between the predicted and observed matrix in the parent population (test of exact fit). Hence, a good fit between the observed and predicted matrices is indicated by the impossibility of rejecting the null hypothesis (Ho). This chi-square test is the only indicator of adequacy that follows a known distribution: the distribution of chi-square with $[p(p+1)/2 - q]$ degrees of freedom (p =number of observed variables, q =number of estimated parameters). A general consensus in the scientific community is to consider that the model fits the data when the probability of the chi-square test has a value of $P > .05$.

The estimation algorithm (ML) and the chi-square test rely on the assumption of the multinormality of the variables. The multinormality assumption can be tested by calculating either coefficients of symmetry and concentration or the coefficient of Mardia, which takes all the variables into account simultaneously.

3.3.3. Sample size

In general, it is advisable to have a sample size including at least about 10 observations by estimated parameter [61]. If we take into account that the fit of the model is assessed by a chi-square statistic that is calculated using the sample size (n) and the fit function, there can be a lack of sensitivity (not rejecting the null hypothesis) when the sample size is small (i.e., less than 100); on the contrary, the test can become too much sensitive (arousing the type II error: rejecting wrongly the null hypothesis) when the sample size is higher than 1000. It is henceforth recommended, as a rule of thumb, to work with sample including at least the number of observations corresponding to the number of observations necessary to get a reliable estimation of the parameters. However, according to the sensitivity of the test of fit, a sample size of several hundred will be optimal to avoid a lack — reciprocally an excess — of sensitivity [61]. In fMRI, it means that the number of observations will depend on the subject and scan number. All these information are based upon recommendations in the framework of the maximum-likelihood algorithm. Recent developments in the use of Bayesian algorithm (Markov Chain Monte Carlo with Gibbs sampler and/or Metropolis Hastings) to estimate SEM parameters have proved to give consistent estimations even with samples smaller than 100 observations [69].

3.4. Identifying a theoretical model

The identification of a theoretical model is a determining issue in the resolution of an analysis by SEM. A problem of model identification means that the software used is unable to generate single estimates of the parameters, which will lead it to reject the model. Thus, identifying a model implies that it is theoretically possible to calculate a single estimate of each one of its parameters (coefficient of correlation, covariance or regression). This question is partially important with the complexity of the tested model. The more the theoretical model becomes complex, the more the difficulty of its identification increases. The first condition necessary to

identify a model is that there are at least as many observations as parameters to be estimated. The second is the absence of multicollinearities between the observed variables. If some of them are too strongly correlated, that reduces the number of observations. More largely, the problem of the identification of a model is relied on the basic concept of degrees of freedom.

As previously noted, we want a structural model that is able to reproduce the theoretical covariance matrix (predicted) from the observed covariance matrix. Thus, the model must be identifiable. A model is said to be identified if it is theoretically possible to derive a unique estimate of each parameter. If not, the model is not identified. For that, we need to compare the number of parameters to be estimated (unknown) with the number of observed variables (known). In general, the simplest structural model will be always preferred because it has fewer parameters to be estimated, it is more economical and more stable and it will have a greater number of degrees of freedom, which makes it more difficult to reject the null hypothesis. We will, thus, seek to estimate each parameter in a single way (a unique solution). In the model just identified, the number of observed variables equals the number of parameters to be estimated; the model, called the saturated model, gives a trivial solution for the estimation of the model parameters and, thus, is noninformative. In the underidentified model, the number of observed variables is lower than the number of parameters to be estimated and the model tries to estimate more coefficients than there is information available in the matrix of data; the estimation is impossible because there are too many unknown parameters. In the overidentified model, the number of observed variables is higher than the number of parameters to be estimated. This model is optimal since we have fewer parameters to estimate than we have observed variables; thus, the model is identifiable. To identify a model, it is often necessary to fix or constrain certain parameters, to fix variances of error of observed variables and to fix coefficients of regression measuring the known effects with certainty.

3.4.1. Error variance (or residual variance)

Error variances represent unmeasured influences that are outside the model. They indicate a proportion of the total variance of a variable not taken into account by the other variables of the model [40,70,71]. Finding that a certain brain area has no residual variance would imply that all variance in this area is taken into account by connections with other areas in the model of measurement, which seems unlikely in neural systems. This error variance generally comes from the influence of brain areas not included within the model or even from the influence of an area on it. In practice, error variance can be fixed using rough estimations obtained via multiple regression, which reduces the number of parameters to be estimated in the model.

3.5. Evaluating the model's adequacy to the data

The chi-square test presented above is the only test based on frequentist inference (null hypothesis) available in SEM.

The major drawback of the chi-square test is its dependency on sample size and, to a lesser extent, on the number of parameters introduced in the model. There are other indexes of fit of the model, which are based on error of approximation, which is indicated by the difference between the matrix of observed covariance and the matrix of estimated covariance. These indexes can adapt to the sample size and to the nature of the data; they are based on the total population or the sample, and they can support a simple model or not penalize a complex one.

Contrary to models just perfectly identified ($N_{\text{obs}}=N_{\text{par}}$), models that were overidentified ($N_{\text{obs}}>N_{\text{par}}$) never perfectly adjust the observed data. Thus, the degree of adequacy of the models must be estimated. For that, we use indexes of adequacy or indicators. However, such indicators often evaluate an overall fit based on averaged values; thus, it is extremely probable that certain parts of the model must be slightly adjusted. In this case, a set of indicators will be necessary to validate the adequacy of the model. Each indicator will generally reflect a particular aspect of the fit of the model; this is why several indicators are often used to test the fit of two matrices. By the way, numerous studies based on simulated data have shown that different indicators can be more or less sensitive to different types of misfit or to different types of bias (sample size, deviation from multinormality); it is henceforth recommended to establish the decision of model acceptance (or rejection) by considering a set of indicators rather than one or two indicators isolated [72,73]. Thus, from the theoretical model, we will estimate path coefficients that will be validated on the basis of a chi-square test and by the means of various indicators [56,61,72,74,75].

Briefly, absolute fit indexes evaluate how well a theoretical model correctly reproduces observed data. Incremental fit indexes (or indexes of comparison) measure the fit improvement by comparing the tested model with a more restrictive basic model. Indexes of parsimony allow one to avoid under- or overestimating a given model and to determine the most suitable model.

3.5.1. Absolute fit indexes

There is no perfect absolute index of measurement (gold standard) for evaluating the improvement of fit [72,75,76]. All indexes presented in Section 3.5 are approximation indexes that test the quality of fit.

3.5.2. Goodness-of-fit indexes

In principle, goodness-of-fit indexes compare the matrix of covariance predicted by the model with that of a "saturated" model, which would perfectly predict observed data. We first obtain a value of χ^2 :

$$\chi^2 = (N - 1)F_{\min}, \quad (1)$$

where N is the sample size and F_{\min} is the minimal value of the minimization function obtained through the estimation algorithm used (in general maximum likelihood).

We use the test based on the minimization function χ^2 or test of exact fit. Ideally, the test result should be nonsignificant. This index follows a chi-square distribution; hence, it is possible to determine a P value associated with the chi-square value and the number of degrees of freedom of the tested model. The chi-square is biased by the sample size because sample size (n) enters into the computation of this index. Thus, this index presents two disadvantages: its value is affected by (a) sample size and (b) the number of parameters in the tested model. Furthermore, the chi-square is sensitive to the magnitude of the correlations. The stronger the correlations, the greater the values of chi-square and, thus, the larger the difference between observed correlations and those predicted by the model [67].

During the last 30 years, new indexes that avoid the dependencies on sample size and the number of parameter have been designed. Their authors have tried to find indexes that have known intervals of variation and for which threshold values can be found, which allow one to objectively decide whether to accept or reject the model. In the last 10 years, the limitations of these indexes, demonstrated through simulation studies, resulted in the approach of using several references and comparing their respective values for the tested model [72,73]. This point will be discussed after presenting the main indexes, regrouped under the rationale of their construction principle.

3.5.3. Approaches based on the comparison of the fit of reference models

Two reference models are the best model (saturated model) and the worst model (model of independence). For the independence model, we assume that there is no relation between variables. Covariance values are fixed at zero and only the values of variances are estimated; thus, this model can be considered as the model presenting the worst fit to the data. The ratio of the model tested and model of independence is particularly instructive because it shows improvement made by the model tested. These indicators are based on the relationship between the χ^2 of the tested model and the χ^2 of the model of independence. Ratio values can theoretically vary from 0 to 1: We consider that values about 0.90 indicate a good adjustment. Normed fit index (NFI) and relative fit index (RFI) [75] correspond to the ratio between the χ^2 of the considered models. RFI is corrected by the number of degrees of freedom. Incremental fit index [77] and Tucker–Lewis index (TLI) [78] are based on the ratio between the difference of χ^2 of the model of independence and the tested model and the difference of χ^2 of the basic model and the number of degrees of freedom of the model. Moreover, TLI is corrected for the number of degrees of freedom. We will be able to neglect the comparative fit index in this first approach. NFI and TLI are two indexes that can be used to judge the fit improvement when comparing two models designed by the researcher. We discuss this issue when presenting the model comparison.

The goodness-of-fit index (GFI) can be considered to estimate the proportion of variance of the observed matrix that is explained by the model [79]. Adjusted GFI corrects GFI for the number of degrees of freedom. These indicators vary

theoretically between 0 and 1. Values of at least 0.90 indicate a good adjustment. Parsimony GFI (PGFI) is the product of GFI and the ratio accounting for the economic aspect of the model, that is, (degree of freedom of the model)/(degree of freedom of the basic model). PGFI supports the more economic models.

The root-mean-square residual (RMR) estimates the average of residues. Its interpretation is made possible if its initial matrix is a correlation matrix. SRMR corresponds to standardized RMR; it is interpretable if its initial matrix is a variance/covariance matrix.

3.5.4. Approaches based on the gap between observed and estimated matrixes

The following indicators try to standardize the indicators that are calculated from the differences between the observed matrix and the estimated matrix. These indexes test the “badness” of fit of the model. F_{\min} is the minimum value of the difference function between the sample reached at the time of the estimate and the estimated matrix. F_0 is the value of the difference function in the parent population. It is especially used in the form of the root-mean-square error of approximation (RMSEA). RMSEA represents the average difference, by degree of freedom, expected in the population and not in the sample. RMSEA is particularly important because it is relatively independent of sample size and the number of parameters used in the model [80]. It is given with a confidence interval of 90%.

RMSEA combines several properties. It is an index of parsimonious adequacy because RMSEA includes a correction for the complexity of the model. It will not seek to approach a centered distribution (as does chi-square), but rather a non-centered distribution, which does not require having a true null hypothesis. It is a test of close fit based on the hypothesis that in the parent population, the gap between the model and the data can be different from zero (a hypothesis of exact fit that is very restrictive). This means that an adequate fit between the model and the observed sample need not be perfect (close fit). It is an index of badness of fit, that is, a bad specification of the model: A zero indicates a good fit, whereas higher values indicate a bad fit. Thus, the smaller RMSEA, the better. Otherwise, the model will be only a rough approximation of reality and not an exact copy. Because RMSEA is relatively independent of sample size and the number of parameters, its values can generally be considered independently of the data and model characteristics. These properties allowed Browne and Cudeck [80] to give general reference thresholds, now widely accepted by the SEM community: $RMSEA < 0.05$ indicates a good adequacy of the model and the null hypothesis will not be rejected; $0.05 < RMSEA < 0.08$ constitutes a reasonable error of approximation, and for $RMSEA > 0.10$, the model’s adequacy is considered to be weak.

3.5.5. Indexes of parsimony (absolute and incremental corrected indexes)

Indexes of parsimony balance two opposite constraints: they minimize the number of coefficients to be estimated and

maximize the degree of fit of the model. They are used to prevent models from having too many parameters; they detect if a bad fit of the model does not arise from a lack of free parameters (too many fixed parameters). Thus, these indexes can be used to find the most parsimonious of several equivalent models. They measure the lack of fit due to the model constraints. For example, the scaled chi-square of Jöreskog and Sörbom [79] can detect models that are over- or underadjusted: It indicates which of several alternative models is the most parsimonious.

3.6. Comparing models

The current canonical approach of SEM, of testing only one model, has been evolving towards a model comparison approach. The models in competition can be defined before the experimentation (theory-driven process) or can be constructed through an improvement process while analyzing the data (data-driven process). This way of handling the models tends to reduce the distinction between a purely confirmatory approach (only one model tested) and exploratory approach (like in classical factor analysis, where the aim is to explore the data structure without imposing any constraint on the number of factors or on the relationships between the observed variables and the factors). The interest in comparing several models and/or the existence of equivalent models (models for which the fit indicators have exactly the same values, hence the relationships between variables representing different causal networks) has led to a new paradigm that compares a set of plausible models. This new paradigm will be discussed after describing the classical model comparison approach starting with the data-driven approach: the improving of a model.

3.6.1. Respecifying the theoretical model (indexes of modification)

Questions arise when we try to improve the fit of the structural model to empirical data or to the theory that underlies it. Relations supported by theoretical assumptions cannot be modified while relations supported by empirical assumptions, based on previous results, can be modified if theoretically justified. Indexes exist to identify variables that are worth the effort of respecification. Indeed, it is possible to add or withdraw paths based on empirical criteria. Maximum Lagrangian multipliers estimate of how much the chi-square test would decrease if a particular path that was fixed at zero were free to vary. However, maximum Lagrangian multipliers are sensitive to the sample size; changes are more likely to be significant with large samples. If the amplitude of the expected effect is low, the statistical significance of this indicator might reflect size rather than the amplitude of required effect. Thus, modification indexes represent the amount of decrease in chi-square if one or more additional parameters of covariance were considered. A value of the modification index higher than 3.84 (the value of the chi-square distribution with one degree of freedom correspond-

ing to a probability of .05) would show a significant chi-square reduction if we added a specified relation in model.

Indexes of modification are sometimes delicate even if their significance is easy to understand. Initially, such indicators are provided for all the parameters not introduced within the model, including aberrant parameters such as covariances between latent variables and error variances. More dangerous are the parameters that seem plausible but cannot be interpreted. Thus, error covariances often have high values. In certain cases, the covariances make sense, for example, when testing and retesting, when conducting consecutive tests, halo effects, etc. In such cases they can be introduced into the model. However, the user often cannot give a reliable interpretation of the error covariance between observed variables. Being able to interpret the error covariance between observed variables is more important than decreasing the χ^2 value in order to accept the model. In addition, the values of the indexes are not independent: if we add one parameter not yet introduced into the model, the indexes of modification of the remaining parameters will be modified. Adding parameters whose indexes of modification are not very high may not make much of a change in the quality of fit of the model. Moreover, adding additional parameters will adversely affect indicators that assess the economy of the model. Thus, it is important

- to introduce only parameters that are justified on theoretical and/or methodological grounds.
- not to introduce several parameters at once, but rather, to introduce one by one new parameters for which the index of modification is high and interpretable, in order to see their effect on the remaining indexes of modification of the other parameters that were not yet introduced [76].

Examining the standardized residues of the covariance matrix might suggest that there is an error in the predictions of the model. Residues exceeding ± 2.58 (the value of the Z distribution for $P=.01$) should be regarded as significant. Residues with high values indicate that the relationship between the two variables is insufficiently accounted for by the model. Such high residual values can suggest that the relationship may be improved by adding parameters (representing direct and/or indirect effects) to the model.

The main drawback of these data-driven techniques is that they result in strong biases in the fit indicator values and their interpretation. A strong test of the respecification would be to test the improved model with data from a new sample — a difficult and costly effort. One could, instead, divide the sample in two subsamples: use one to get information for improving the model and the other to test the improved model.

3.6.2. Comparing models defined a priori

The simplest situation is the comparison of nested models. Model A is said to be nested in Model B when it is possible to

pass from Model A to Model B only by freeing some parameters. SEM can explicitly compare the adequacy of nested models. The two nested models can be easily specified by most software by introducing constraints on the parameters. For example, if we want to compare two models, one of which contains a parameter and the other does not, one simply leaves the parameter free in the one model and constrains it to equal zero in the other. The significance of the difference between the χ^2 of the two nested models is tested. The number of degrees of freedom of the test is the difference between the numbers of degrees of freedom of the two models. If the test is significant, the H_0 of equality can be rejected and one can conclude that one of the models more adequately fits the data: Notice that this conclusion is true only if the nesting model fits the data; that is, the nesting model is correct.

3.6.3. Comparing independent groups

Between-group comparisons are a precious feature of SEM for fMRI studies [32,39,42,47,48,65,76,81], as it provides the means to test the effect of different experimental conditions when the data come from independent groups. We invite the reader to consult the article of de Marco et al. [4], noted above, for an example. That study concerned changes in effective connectivity that occurred during incidental and intentional perception of the same fearful faces. Briefly, SEM was used to construct a pathway model that could account for fMRI data in all regions of interest for the perception of fearful faces. Adjusted fMRI signals in the regions of interest extracted from the data set were entered as variables in the structural model, which was assessed by minimizing the difference between observed and predicted covariances of the fMRI data, according to the maximum-likelihood algorithm. In the analysis, the variables are considered in terms of their covariance structure.

Typically, in SEM, between-group comparisons use a model comparison approach. Instead of analyzing only one covariance matrix, the analysis uses stacked matrices, one for each experimental group. In a nonconstrained model, there is one value for each path coefficient and each group. Also in this approach, constraints are introduced on the estimations of the parameters, usually constraints of equality; there is only one value for each parameter and it is common to all groups. For example, the estimate of the values of a path coefficient can be constrained to be equal in the experimental groups. The between-group comparison, therefore, amounts to a comparison between a constrained (fixed parameters) and a nonconstrained (free parameters) model. The model comparison proceeds as follows. First, the algorithm estimates the specific parameter value for each path and each group and the model is examined to ensure that the hypothesized causality network fits the data. Then, the parameters for each group are forced to equality. Finally, the significance of the difference between the two models is tested. Since the constrained model is nested in the nonconstrained model, the χ^2 of the difference between the χ^2 of the two models can be used to test the significance of the difference between them. If the models differ, then it must be that the experimental groups differ in terms of path connectivity.

In other words, if the fit of the constrained model (using common values for the parameters) is significantly different from the fit of the unconstrained model (using specific/different values for the parameters in each group), then we can conclude that there is a difference between the parameters (i.e., the causal pathways) of the experimental groups and the differences must be taken into consideration to model the covariance matrix.

In order to account for the overall difference between the experimental groups, each pair of parameters from the experimental groups can be compared (pairwise comparison). The test, which follows a Z distribution, is based on the differences between the parameter values divided by the standard error of measurement of these differences [82].

3.7. Procedure for model specification

This approach was first mentioned by MacCallum (1986) and MacCallum, Wegener, Uchino, and Fabrigar (1993). The model specification approach considers a set of models comprising common or obligatory parameters (they will be present in all the studied models) and optional parameters. Optional parameters may or may not be present in some or all of the models. If the number of optional parameters is p , then the total number of different models will be 2^p : for one parameter, there are two models (with and without the parameter); for two parameters, there are four models, and so forth. Once the unidentified models or models comprising inadmissible values are eliminated, we obtain a set of “plausible” models that contain the obligatory and optional parameters. To sort them out, we will use the Kullback and Leibler (Burnham & Anderson, 1998) approach that is based on information theory. The issue is to retain the best model in terms of the trade-off between the quality of the adequacy of fit of the model to the data and the economic character (number of parameters) of the model. To do so, we will use the indicators built within the framework of the information theory, in particular the criterion of information of Akaike (Akaike Information Criterion; about the use of this indicator and model selection in SEM, see Raftery, 1993). Because they are “badness-of-fit indicators,” high values indicate bad models. The approach is particularly heuristic: It bridges clearly exploratory approaches (there is no a priori model) and clearly confirmatory approaches (there is only one a priori model) by exploring “plausible” models. The essential idea of the information-theory data analysis is that, although the “real” model behind the data is not knowable, we can construct models that could plausibly generate the data. Plausibility models are assessed by the information that they take into account.

3.7.1. Choosing an algorithm of estimate

The main softwares propose different algorithms to estimate the parameters. The maximum-likelihood algorithm is most frequently used in structural modeling because its parameter estimates are highly robust. Nevertheless, questions of estimate bias caused by variations in the conditions of validity (i.e.,

multinormality of the data), reports of the absence of convergence and the occurrence of aberrant estimates (e.g., negative variance) have resulted in the development of other estimation algorithms. Some of them provide reliable starting values for other more sophisticated algorithms, such as maximum-likelihood algorithms (e.g., generalized least squares). Others circumvent the necessity of the multinormality assumption; for example, skewed distributions are not problematical. The “weighted least squares” or “asymptotic distribution-free” algorithm estimates weights for each covariance to correct for asymmetric characteristics of the distributions of each pair of variables: It gives a more reliable estimate of the parameters and of the tests of fit when the distributions are asymmetrical (Browne, 1984). Weighted algorithms require large sample sizes. The difficulties and biases of estimate noted earlier, as well as the absence of tests of inference for certain indicators (e.g., the coefficient of determination R), resulted in including bootstrapping procedures within the software of structural models. Bootstrapping procedures have the advantage of providing distributions for all the parameters, distributions taking into account the specificities of the data. As Bollen and Stine (1993) showed, the relevance of bootstrapping must be clear. Finally, 20 years ago, the Bayesian approach appeared to provide a pragmatic improvements in the procedures for estimating parameters within the framework of complex models (e.g., multilevel models) (Gelman, Carlin, Stern, & Rubin, 2004). In the case of the structural models, the Bayesian approach can yield robust estimates, especially with small samples. It also allows a priori constraints to be placed on the distributions in order to avoid problems of estimate (e.g., requiring the variances to be positive). The algorithm obtains a a posteriori distribution of all the usually estimated parameters. We can also obtain, in supplement, the distribution of statistics of complex parameters, such as direct and indirect effects, which are not provided by the usual algorithms, such as the maximum-likelihood algorithm.

3.8. Conclusion

SEM represents a linear method for multivariate analysis of fMRI data and has been developed to simultaneously examine ratios of multiple causality in an experimental design. SEM attempts to explain a covariance structure within an anatomical constrained model. Combined with the concept of effective connectivity, SEM can provide information on the strength and direction of the functional interactions that take place between identified regions of a putative network. It should be remembered that SEM is a confirmatory model of analysis and/or a theoretical model: thus, each relation in the model that is tested must be grounded in a theory or on empirical bases.
